17 Higher Order Function Examples

17.1 Chapter Introduction

The previous two chapters introduced the concepts of first-class and higher-order functions and their implications for Haskell programming.

This chapter looks at additional examples that use these higher-order programming concepts.

The Haskell module for this chapter’s code is in `HigherOrderExamples.hs` except for the revised rational arithmetic module.

17.2 List-Breaking Operations

In a previous chapter we looked at the list-breaking functions `take` and `drop`. The Prelude also includes several higher-order list-breaking functions that take two arguments, a predicate that determines where the list is to be broken and the list to be broken.

Here we look at Prelude functions `takeWhile` and `dropWhile`. As you would expect, function `takeWhile` “takes” elements from the beginning of the list “while” the elements satisfy the predicate and `dropWhile` “drops” elements from the beginning of the list “while” the elements satisfy the predicate. The Prelude definitions are similar to the following:

```haskell
takeWhile :: (a -> Bool) -> [a] -> [a]
-- takeWhile in Prelude
takeWhile p [] = []
takeWhile p (x:xs)
  | p x = x : takeWhile p xs
  | otherwise = []

dropWhile :: (a -> Bool) -> [a] -> [a]
-- dropWhile in Prelude
dropWhile p [] = []
dropWhile p xs@(x:xs')
  | p x = dropWhile p xs'
  | otherwise = xs
```

Note the use of the pattern `xs@(x:xs')` in `dropWhile'`. This pattern matches a non-nil list with `x` and `xs'` binding to the head and tail, respectively, as usual. Variable `xs` binds to the entire list.

As an example, suppose we want to remove the leading blanks from a string. We can do that with the expression:

```haskell
dropWhile ((==) ' ')
As with `take` and `drop`, the above functions can also be related by a “law”. For all finite lists `xs` and predicates `p` on the same type:

\[
\text{takeWhile } p \text{ xs }++ \text{ dropWhile } p \text{ xs } = \text{xs}
\]

Prelude function `span` combines the functionality of `takeWhile` and `dropWhile` into one function. It takes a predicate `p` and a list `xs` and returns a tuple where the first element is the longest prefix (possibly empty) of `xs` that satisfies `p` and the second element is the remainder of the list.

\[
\text{span} :: (a \to \text{Bool}) \to [a] \to ([a],[a]) \quad \text{-- span in Prelude}
\]

\[
\text{span} _\, \text{x}@[] = (\text{x}, \text{x})
\]

\[
\text{span} _\, p \text{x}@\text{(x:x\text{'})} =
\begin{align*}
| & p \, x & = \text{let } \text{ys}, \text{zs} = \text{span} _\, p \text{x' in } (x:\text{ys}, \text{zs}) \\
| & \text{otherwise} & = ([], \text{x})
\end{align*}
\]

Thus the following “law” holds for all finite lists `xs` and predicates `p` on same type:

\[
\text{span } p \text{ xs }== (\text{takeWhile } p \text{ xs}, \text{dropWhile } p \text{ xs})
\]

The Prelude also includes the function `break`, defined as follows:

\[
\text{break} :: (a \to \text{Bool}) \to [a] \to ([a],[a]) \quad \text{-- break in Prelude}
\]

\[
\text{break} _\, p = \text{span} (\text{not } . \ p)
\]

### 17.3 List-combining operations

In a previous chapter, we also looked at the function `zip`, which takes two lists and returns a list of pairs of the corresponding elements. Function `zip` applies an operation, in this case `tuple-construction`, to the corresponding elements of two lists.

We can generalize this pattern of computation with the function `zipWith` in which the operation is an argument to the function.

\[
\text{zipWith} ' :: (a\to b\to c) \to [a]\to[b]\to[c] \quad \text{-- zipWith in Prelude}
\]

\[
\text{zipWith} ' z (x:xs) (y:ys) = z x y : \text{zipWith} ' z xs ys
\]

\[
\text{zipWith} ' _ _ _ = []
\]

Using a lambda expression to state the tuple-forming operation, the Prelude defines `zip` in terms of `zipWith`:

\[
\text{zip} ' :: [a] \to [b] \to [(a,b)] \quad \text{-- zip}
\]

\[
\text{zip} ' = \text{zipWith} ' (\text{x y }\to (x,y))
\]

Or can be written more simply as:

\[
\text{zip} ' ' ' :: [a] \to [b] \to [(a,b)] \quad \text{-- zip}
\]

\[
\text{zip} ' ' ' = \text{zipWith} ' (,)
\]
The `zipWith` function also enables us to define operations such as the scalar product of two vectors in a concise way.

\[
sp :: \text{Num } a \Rightarrow [a] \rightarrow [a] \rightarrow a
sp \, xs \, ys = \text{sum}' \,(\text{zipWith}' \, \text{(*)} \, \, xs \, \, ys)
\]

The Prelude includes versions of `zipWith` that take up to seven input lists: `zipWith3` \(\ldots\) `zipWith7`.

### 17.4 Rational Arithmetic Revisited

Remember the rational number arithmetic package developed in an earlier chapter. In that package’s `Rational` module, we defined a function `eqRat` to compare two rational numbers for equality using the appropriate set of integer comparisons.

\[
eqRat :: \text{Rat} \rightarrow \text{Rat} \rightarrow \text{Bool}
eqRat \, x \, y = (\text{numer} \, x) \ast (\text{denom} \, y) == (\text{numer} \, y) \ast (\text{denom} \, x)
\]

We could have implemented the other comparison operations similarly.

Because the comparison operations are similar, they are good candidates for us to use a higher-order function. We can abstract out the common pattern of comparisons into a function that takes the corresponding integer comparison as an argument.

To compare two rational numbers, we can express their values in terms of a common denominator (e.g. `\text{denom} \, x \ast \text{denom} \, y`) and then compare the numerators using the integer comparisons. We can thus abstract the comparison into a higher-order function `compareRat` that takes an appropriate integer relational operator and the two rational numbers.

\[
\text{compareRat} :: (\text{Int} \rightarrow \text{Int} \rightarrow \text{Bool}) \rightarrow \text{Rat} \rightarrow \text{Rat} \rightarrow \text{Bool}
\text{compareRat} \, r \, x \, y = r \,(\text{numer} \, x \ast \text{denom} \, y) \,(\text{denom} \, x \ast \text{numer} \, y)
\]

Then we can define the rational number comparisons in terms of `compareRat`. (Note that we redefine function `eqRat` from the package in the earlier chapter.)

\[
\begin{align*}
\text{eqRat, neqRat, ltRat, leqRat, gtRat, geqRat} & :: \text{Rat} \rightarrow \text{Rat} \rightarrow \text{Bool} \\
\text{eqRat} & = \text{compareRat} \,(==) \\
\text{neqRat} & = \text{compareRat} \,(/=) \\
\text{ltRat} & = \text{compareRat} \,(<) \\
\text{leqRat} & = \text{compareRat} \,(\leq) \\
\text{gtRat} & = \text{compareRat} \,(>) \\
\text{geqRat} & = \text{compareRat} \,(\geq)
\end{align*}
\]

The Haskell module for the revised rational arithmetic module is in `RationalHO.hs`. The module `TestRationalHO.hs` is an extended version of the standard test script from Chapter 12 that tests the standard features of
the rational arithmetic module plus \texttt{eqRat}, \texttt{neqRat}, and \texttt{ltRat}. (It does not currently test \texttt{leqRat}, \texttt{gtRat}, or \texttt{geqRat}.)

17.5 Merge Sort

We defined the insertion sort in a previous chapter. It has an average-case time complexity of $O(n^2)$ where $n$ is the length of the input list.

We now consider a more efficient function to sort the elements of a list into ascending order: \textit{merge sort}. Merge sort works as follows:

- If the list has fewer than two elements, then it is already sorted.
- If the list has two or more elements, then we split it into two sublists, each with about half the elements, and sort each recursively.
- We merge the two ascending sublists into an ascending list.

We define function \texttt{msort} to be a polymorphic, higher-order function that has two parameters. The first (\texttt{less}) is the comparison operator and the second (\texttt{xs}) is the list to be sorted. Function \texttt{less} must be defined for every element that appears in the list to be sorted.

\begin{verbatim}
msort :: Ord a => (a -> a -> Bool) -> [a] -> [a]
msort _ [] = []
msort less xs = merge (msort less ls) (msort less rs)
  where n = (length xs) `div` 2
        (ls,rs) = splitAt n xs
        merge [] ys = ys
        merge xs [] = x
        merge ls@(x:xs) rs@(y:ys)
          | less x y = x : merge xs rs
          | otherwise = y : merge ls ys
\end{verbatim}

By nesting the definition of \texttt{merge}, we enabled it to directly access the the parameters of \texttt{msort}. In particular, we did not need to pass the comparison function to \texttt{merge}.

Assuming that \texttt{less} evaluates in constant time, the time complexity of \texttt{msort} is $O(n \log(n))$, where $n$ is the length of the input list.

- Each call level requires splitting of the list in half and merging of the two sorted lists. This takes time proportional to the length of the list argument.
- Each call of \texttt{msort} for lists longer than one results in two recursive calls of \texttt{msort}.
- But each successive call of \texttt{msort} halves the number of elements in its input, so there are $O(\log(n))$ recursive calls.
So the total cost is $O(n \log(n))$. The cost is independent of distribution of elements in the original list.

We can apply \texttt{msort} as follows:

\[
\texttt{msort} \ (<) \ [5, 7, 1, 3]
\]

Function \texttt{msort} is defined in curried form with the comparison function first. This enables us to conveniently specialize \texttt{msort} with a specific comparison function. For example,

\[
\texttt{descendSort :: Ord a} \Rightarrow \texttt{[a] -> [a]}
\]

\[
\texttt{descendSort} = \texttt{msort} \ (\backslash x \ y \rightarrow x \ > \ y)
\]

17.6 Exercises

TODO: Allocate among chapters

1. Suppose you need a Haskell function \texttt{times} that takes a list of integers (type \texttt{Integer}) and returns the product of the elements (e.g, \texttt{times \ [2,3,4]} returns \texttt{24}). Define the following Haskell functions.

   a. Function \texttt{times1} that uses the Prelude function \texttt{foldr}(or \texttt{foldr'}) from this chapter).

   b. Function \texttt{times2} that uses backward recursion to compute the product. (Use recursion directly. Do not use the list-folding Prelude functions such as \texttt{foldr} or \texttt{product}.)

   c. Function \texttt{times3} that uses forward recursion to compute the product. (Hint: use a tail-recursive auxiliary function with an accumulating parameter.)

   d. Function \texttt{times4} that uses function \texttt{foldl'} from the Haskell library \texttt{Data.List}.

2. For each of the following specifications, define a Haskell function that has the given arguments and result. Use the higher order library functions (from this chapter) such as \texttt{map}, \texttt{filter}, \texttt{foldr}, and \texttt{foldl} as appropriate.

   a. Function \texttt{numof} takes a value and a list and returns the number of occurrences of the value in the list.

   b. Function \texttt{ellen} takes a list of character strings and returns a list of the lengths of the corresponding strings.

   c. Function \texttt{ssp} takes a list of integers and returns the sum of the squares of the positive elements of the list.

3. Suppose you need a Haskell function \texttt{sumSqNeg} that takes a list of integers (type \texttt{Integer}) and returns the sum of the squares of the negative values in the list.
Define the following Haskell functions. Use the higher order library functions (from this chapter) such as \texttt{map}, \texttt{filter}, \texttt{foldr}, and \texttt{foldl} as appropriate.

a. Function \texttt{sumSqNeg1} that is backward recursive. (Use recursion directly. Do not use the list-folding Prelude functions such as \texttt{foldr} or \texttt{sum}.)

b. Function \texttt{sumSqNeg2} that is tail recursive. (Use recursion directly. Do not use the list-folding Prelude functions such as \texttt{foldr} or \texttt{sum}.)

c. Function \texttt{sumSqNeg3} that uses standard Prelude functions such as \texttt{map}, \texttt{filter}, \texttt{foldr}, and \texttt{foldl}.

d. Function \texttt{sumSqNeg4} that uses list comprehensions (Chapter 7).

4. Define a Haskell function

\begin{verbatim}
  total :: (Integer -> Integer) -> Integer -> Integer
\end{verbatim}

so that \texttt{total f n} gives \(f \ 0 + f \ 1 + f \ 2 + \ldots + f \ n\).

5. Define a Haskell function

\begin{verbatim}
  removeFirst :: (a -> Bool) -> [a] -> [a]
\end{verbatim}

so that \texttt{removeFirst p xs} removes the first element of \texttt{xs} that does have the property \texttt{p}.

6. Define a Haskell function

\begin{verbatim}
  removeLast :: (a -> Bool) -> [a] -> [a]
\end{verbatim}

so that \texttt{removeLast p xs} removes the last occurrence of element of \texttt{xs} that has the property \texttt{p}.

How could you define it using \texttt{removeFirst}?

7. Define a Haskell function \texttt{map2} that takes a list of functions and a list of values and returns the list of results of applying each function in the first list to the corresponding value in the second list.

8. Define a Haskell function \texttt{fmap} that takes a value and a list of functions and returns the list of results from applying each function to the argument value. (For example, \texttt{fmap 3 [[(*2)], [(+) 2]]} yields \([6,5]\).)

9. Define a Haskell function \texttt{composeList} that takes a list of functions and composes them into a single function. (Be sure to give the type signature.)

10. A list \texttt{s} is a \textit{prefix} of a list \texttt{t} if there is some list \texttt{u} (perhaps nil) such that \texttt{s ++ u == t}. For example, the prefixes of string \texttt{abc} are \texttt{',a,ab,abc'}.

A list \texttt{s} is a \textit{suffix} of a list \texttt{t} if there is some list \texttt{u} (perhaps nil) such that \texttt{u ++ s == t}. For example, the suffixes of \texttt{abc} are \texttt{abc, bc, c, and ".}
A list \( s \) is a segment of a list \( t \) if there are some (perhaps nil) lists \( u \) and \( v \) such that \( s = u \cdot t \cdot v \). For example, the segments of string \( \text{abc} \) consist of the prefixes and the suffixes plus \( \text{b} \).

Define the following Haskell functions. You may use functions appearing early in the list to implement later ones.

a. Define a function \( \text{prefix} \) such that \( \text{prefix} \, \text{xs} \, \text{ys} \) returns \( \text{True} \) if \( \text{xs} \) is a prefix of \( \text{ys} \) and \( \text{False} \) otherwise.

b. Define a function \( \text{suffixes} \) such that \( \text{suffixes} \, \text{xs} \) returns the list of all suffixes of list \( \text{xs} \). (Hint: Generate them in the order given in the example of \( \text{abc} \) above.)

c. Define a function \( \text{indexes} \) such that \( \text{indexes} \, \text{xs} \, \text{ys} \) returns a list of all the positions at which list \( \text{xs} \) appears in list \( \text{ys} \). Consider the first character of \( \text{ys} \) as being at position 0. For example, \( \text{indexes} \, \text{ab} \, \text{abaabbab} \) returns \( [1, 4, 7] \). (Hint: Remember functions like \( \text{map} \), \( \text{filter} \), \( \text{zip} \), and the functions you just defined?)

d. Define a function \( \text{sublist} \) such that \( \text{sublist} \, \text{xs} \, \text{ys} \) returns \( \text{True} \) if list \( \text{xs} \) appears as a segment of list \( \text{ys} \) and \( \text{False} \) otherwise.

11. Assume that the following Haskell type synonyms have been defined:

\[
\begin{align*}
\text{type Word} & = \text{String} \quad \text{-- word, characters left-to-right} \\
\text{type Line} & = [\text{Word}] \quad \text{-- line, words left-to-right} \\
\text{type Page} & = [\text{Line}] \quad \text{-- page, lines top-to-bottom} \\
\text{type Doc} & = [\text{Page}] \quad \text{-- document, pages front-to-back}
\end{align*}
\]

Further assume that values of type \( \text{Word} \) do not contain any space characters. Implement the following Haskell text-handling functions:

a. \( \text{npages} \) that takes a \( \text{Doc} \) and returns the number of \( \text{Page} \)s in the document.

b. \( \text{nlines} \) that takes a \( \text{Doc} \) and returns the number of \( \text{Line} \)s in the document.

c. \( \text{nwords} \) that takes a \( \text{Doc} \) and returns the number of \( \text{Word} \)s in the document.

d. \( \text{nchars} \) that takes a \( \text{Doc} \) and returns the number of \( \text{Char} \)s in the document (not including spaces of course).

e. \( \text{deblank} \) that takes a \( \text{Doc} \) and returns the \( \text{Doc} \) with all blank lines removed. A blank line is a line that contains no words.

f. \( \text{linetext} \) that takes a \( \text{Line} \) and returns the line as a \( \text{String} \) with the words appended together in left-to-right order separated by space characters and with a newline character \( \backslash n \) appended to the right end of the line. (For example, \( \text{linetext} \, [\text{Robert}, \text{Khayat}] \) yields "Robert Khayat\n".)
g. **pagetext** that takes a **Page** and returns the page as a **String**—applies **linetext** to its component lines and appends the result in a top-to-bottom order.

h. **doctext** that takes a **Doc** and returns the document as a **String**—applies **pagetext** to its component lines and appends the result in a top-to-bottom order.

i. **wordeq** that takes a two **Docs** and returns **True** if the two documents are **word equivalent** and **False** otherwise. Two documents are word equivalent if they contain exactly the same words in exactly the same order regardless of page and line structure. For example, `[["Robert"],["Khayat"]]]` is word equivalent to `[["Robert","Khayat"]]]`.

### 17.7 Acknowledgements

In Summer 2016, I adapted and revised much of this work from the following sources:

- chapter 6 of my *Notes on Functional Programming with Haskell* [Cunningham 2014]
- my notes on *Functional Data Structures (Scala)* [Cunningham 2016] which are based, in part, on chapter 3 of the book *Functional Programming in Scala* [Chiusano 2015]

In Summer 2016, I also added the following, drawing on ideas from [Bird 2015, Ch. 6, 7] and [Thompson 2011, Ch. 11]:

- expanded discussion of combinators and functional composition
- new discussion of the `seq`, `$`, and `$!` operators

In 2017, I continued to develop this work as Chapter 5, Higher-Order Functions, of my 2017 Haskell-based programming languages textbook.

In Summer 2018, I divided the previous Higher-Order Functions chapter into three chapters in the 2018 version of the textbook, now titled *Exploring Languages with Interpreters and Functional Programming*. Previous sections 5.1-5.2 became the basis for new Chapter 15, Higher-Order Functions, section 5.3 became the basis for new Chapter 16, Haskell Function Concepts, and previous sections 5.4-5.6 became the basis for new Chapter 17 (this chapter), Higher-Order Function Examples.

I maintain this chapter as text in Pandoc’s dialect of Markdown using embedded LaTeX markup for the mathematical formulas and then translate the document to HTML, PDF, and other forms as needed.
